1 Bipartite graphs and matchings

Throughout this thesis we will be interested in a specific subclass of graphs known as bipartite graphs. Unless otherwise noted, our algorithms will assume a bipartite structure.

Definition (Bipartite graph). A *bipartite graph* is a graph whose vertices can be partitioned into two set L and R such that all edges connect a vertex $l \in L$ to a vertex $r \in R$. We will denote this graph $G = (L, R, E)$, where E is the edge set.

Figure 1: Examples of bipartite graphs

In Figure 1 we have a bipartite graph with vertex partition given by $L = \{A, B, C, D\}$ and $R = \{E, F, G\}$. All edges in this graph are between a node $l \in L$ and a node $r \in R$. The graph on the right is also bipartite. It may take a little more time to convince yourself that you can partition the vertices into disjoint L and R in a way that maintains the bipartite property. Try it!

Now that we know what we are working with, let's introduce a problem that we'd like to solve on these graphs. We now describe the notion of a matching on a graph. We will define it for arbitrary graphs,

Definition (Matching). Let $G = (V, E)$ be a graph. A subset $M \subset E$ is a *matching* if no two edges in M are incident to the same vertex.

We say that a vertex $v \in V$ is matched with respect to M if it is an endpoint of some edge in M . The following figure shows some examples of different matchings on one of the graphs from Figure 1.

Figure 2: Examples of matchings on a bipartite graph

There many different valid matchings on the graph in Figure 2. Oftentimes, we want to find the largest matching on a graph. (ADD SENTENCE OR TWO ON MOTIVATION FOR MAXIMAL MATCHING.) This leads to the following definition.

Definition (Maximal matching). A *maximal matching* on G is a matching M such that if any other edge not in M is added to M , it is no longer a valid matching. Alternatively put, M is maximal if there is no matching M' such that $M \subset M'$.

Both matchings in Figure 2 are maximal matchings; in each case there are no edges that we can add to M and have that M is still a matching. However, notice that the size of the matchings is different, even though both are maximal on G . This leads to the following definition.

Definition (Maximum matching). A matching M on a graph G is said to be a maximum matching if for all other matchings M' on G , $|M'| \leq |M|$.

In our example, the matching on the right given by $M = \{(A, E), (B, F), (D, G)\}$ is a maximum matching (convince yourself). In general there may be many unique maximum matchings on a graph.

In this section we are interested in general methods for finding maximum matchings on bipartite graphs. One of the fundamental approaches is to look at certain subgraphs called alternating paths. Before we define what these are, let's look at a motivating example. Suppose we have the matching on the left in Figure 2. So $M = \{(A, E), (D, F)\}$. Consider the following sequence of vertices in the graph:

Call this sequence p . Let's perform an operation that we will denote $M \oplus p$, which operates like XOR: add to M each edge in p that isn't in M , and remove from M each edge in p that is in M . This gives us the following segment:

Notice that the size of our matching has grown by 1! In fact, this new matching is exactly the matching given by the graph on the right in Figure 2. This is a general technique in finding

maximum matchings. We want to look for these paths that start and end at unmatched vertices, and whose edges are alternately matched and unmatched. If we can find one of these paths, we will be able to increase the size of matching. We define this formally now.

Definition (Alternating path). Let G be a graph and M some matching on G . An *alternating path* is a sequence of vertices and edges that begins with an unmatched vertex, and whose edges alternate between being in M and not in M .

Definition (Augmenting path). An *augmenting path* is an alternating path that starts and ends on unmatched vertices. When we augment M by an augmenting path p , we use the notation $M \oplus p$.

This motivates a general method for finding a maximum matching on a bipartite graph: just keep looking for augmenting paths, and augment the current matching by that augmenting path. Of course, we need to prove that this in fact gives us a maximum matching. The following theorem says exactly that.

Theorem (Berge, 1957). A matching M on G is a maximum matching if and only if G contains no augmenting paths with respect to M .

This gives us the following framework for finding maximum matchings in bipartite graphs.

ALG 1(G)

```

1   $M := \emptyset$ 
2  while there exists an augmenting path  $p$ 
3       $M := M \oplus p$ 
4  return  $M$ 
```

Note that we have yet to describe the details of this algorithm. Before we do so, we are going to take a step back a bit and look at the maximum matching problem from a slightly different perspective. In doing so, we will develop a language for talking about this problem that will serve us throughout the rest of this thesis. At first, the approach will appear purely pedagogic, but hopefully the reader will understand the significance of it by the end of the thesis.

2 The vertex cover problem

We begin this section by defining a new problem. Again, this is a problem on graphs in general, but we will be restricting our attention to bipartite graphs. This is a good idea for many reasons, but the most pertinent reason is that this problem is NP-complete in the general case.

Definition (Vertex cover). Let $G = (L, R, E)$ be a bipartite graph. A subset $C \subset L \cup R$ is said to be a *vertex cover* if for each $(i, j) \in E$ is such that at least one of $i, j \in C$. C is a *minimum vertex cover* if for any other cover C' , $|C| \leq |C'|$.

Using what we've already learned, we can specify at least one relation between matchings and vertex covers: namely, the vertices of all edges in any maximal matching on a graph forms a vertex cover. Here are some examples of vertex covers on the graph we've been looking at.

You can convince yourself that the cover on the right is a minimum cover. This brings us to an important theorem. We first prove a lemma.

Figure 3: Examples of vertex covers

Lemma 1. Let $G = (L, R, E)$ be a bipartite graph. Let M be a matching on G and C a cover on G such that $|M| = |C|$. Then M is a maximum matching and C is a minimum covering.

Proof. Let M' be a maximum matching on G and C' a minimum covering on G . For each $(i, j) \in M'$, C' must include either i or j , which tells us that $|M'| \leq |C'|$. Then we have

$$|M| \leq |M'| \leq |C'| \leq |C|.$$

Thus, if $|M| = |C|$ we have equalities above, which means that the size of a maximum matching is equal to the size of a minimum covering. \square

Before we prove this, we define a couple of terms. Given a matching M , we say a vertex is *saturated* if it is incident to some edge in M . Also, an M -alternating path is an alternating path with respect to M .

Theorem (König-Egervary). For any bipartite graph G , if M is a maximum matching on G and C is a minimum vertex cover on G , then $|M| = |C|$.

Proof. Let $G = (L, R, E)$ be a bipartite graph, and let M be a maximum matching on G . Furthermore, define

$$A := \{s \in S \mid s \text{ unsaturated}\}$$

and

$$B := \{\text{all vertices connected to nodes in } A \text{ by } M\text{-alternating paths}\}.$$

Let $U = B \cap L$ and $V = B \cap R$. Then we have the following:

1. Every node in V is saturated.
2. $N(U) = V$,

where $N(U)$ denotes the set of all vertices connected to elements of U (the “neighbors” of U). The first claim comes from the fact that, if M is a maximum matching, then our alternating paths starting at nodes in A must have length ≥ 2 , and must have even length (otherwise we would have an augmenting path, which contradicts our assumption that M is a maximum matching). The second comes from that fact that every node in $N(U)$ is connected to vertices in A by an

alternating path.

Now, define $K := (L \setminus U) \cup V$. Every edge in G must have one of its endpoints in K . If not, there would be an edge with one end in U and one end in $R \setminus V$, which contradicts $N(U) = V$. So K is a covering of G . Moreover, $|K| = |M|$, since for each edge in M we've included one of its endpoints in K (the vertices we've chosen are those in $N(U)$ and those in $L \setminus U$). Thus, by the previous lemma, K is a minimum covering. \square

All of this tells us that there is a deep relationship between maximum matchings and minimum vertex covers on bipartite graphs. Given a solution to one, we can turn it into a solution to the other. This is what we seek to accomplish next.

3 Linear programming

For a more detailed treatment on linear programming, we will refer you to (CITE LP SOURCES). For the purposes of this thesis, we will treat linear programming more casually, only requiring few key results. Moreover, we will not be discussing methods of actually solving linear programs.

In the general linear-programming problem, our goal is to optimize some linear function that is constrained by a set of linear inequalities. These problems are ubiquitous in applied math and computer science, as they model a system in which something needs to be optimized according to competing resources. We can express a general *maximization* linear program as

$$\text{maximize} \quad \sum_{j=1}^n c_j x_j \tag{1}$$

$$\text{subject to} \quad \sum_{j=1}^n a_{ij} x_j \leq b_j, \quad i = 1, \dots, m \tag{2}$$

$$x_j \geq 0, \quad j = 1, \dots, n. \tag{3}$$

We call the function in (1) our *objective function*, and the linear inequalities (2) and (3) our constraints. Similarly, a *minimization* linear program takes the form

$$\text{minimize} \quad \sum_{j=1}^n c_j x_j \tag{4}$$

$$\text{subject to} \quad \sum_{j=1}^n a_{ij} x_j \geq b_j, \quad i = 1, \dots, m \tag{5}$$

$$x_j \geq 0, \quad j = 1, \dots, n. \tag{6}$$

Many problems which on the face may not appear to be optimization problems turn out to be easily transcribable into the linear programming formulation. Our goal in this section will be to describe our two problems, maximum matchings and minimum vertex covers, as linear programs.

Let's first turn maximum matching into a linear program. Our goal is to maximize the number of edges in our matching. Our constraint is that no edge is incident to more than one edge in the matching. So for each edge (i, j) , we will need a corresponding x_{ij} . Our objective function is then pretty simple: maximize the number of x_{ij} . Now we need to figure out our constraint equations.

For a fixed node i , the number of edges in the matching incident to i is given by $\sum_j x_{ij}$. So we want that this is ≤ 1 . Similarly, for any node j , we want $\sum_i x_{ij} \leq 1$. This gives us the following linear program.

$$\text{maximize} \quad \sum_{i,j} x_{ij} \tag{7}$$

$$\text{subject to} \quad \sum_j x_{ij} \leq 1, \quad \forall i, \tag{8}$$

$$\sum_i x_{ij} \leq 1, \quad \forall j, \tag{9}$$

$$x_{ij} \in \{0, 1\}. \tag{10}$$
